Objective: Multiple studies conducted over many years have demonstrated that pain is poorly managed in the emergency department (ED). This phenomenon has been referred to in the medical literature as "oligoanalgesia." However, little is known about whether oligoanalgesia occurs in a rural ED. National Ambulatory Care Reporting System data from 2003 for a small rural hospital in Ontario showed patients were satisfied with the amount of pain medicine they received in the ED. We designed a study to replicate a published urban study that investigated the use of analgesia in isolated lower limb injuries. Our objective was to see if oligoanalgesia was also a problem in a rural ED.

Methods: In 2003 we conducted a retrospective chart review of patients who presented to the South Huron Hospital ED with isolated lower extremity injuries for which radiographs of the foot, ankle or both were obtained. Demographics of the ED patients with lower extremity injuries were quantified. Other parameters included whether or not patients received analgesia in the ED; how long it took to get assessed, treated and discharged; whether patients received any analgesia upon discharge; what type of analgesia they received; and whether it required a prescription.

Results: A total of 189 patients met inclusion criteria, with 35 fractures identified (18.5%). Sixty-three percent of patients were male. The average age was 32.6 years. The mean Canadian Emergency Department Triage and Acuity Scale level was 4.4. The mean time to physician assessment was 31.6 minutes. The mean length of time spent in the ED was 74 minutes. Over one-half of the patients received analgesia upon discharge from the ED whether or not they had a fracture. In addition, 73% of the people in the fracture group received analgesia requiring a prescription, versus only 46% in the nonfracture group. Narcotics were used more often in the fracture group than in the nonfracture group (26% v. 6%).

Conclusion: The phenomenon of oligoanalgesia was not observed as often in our rural ED for isolated lower limb injuries, when compared with the published urban study.

Oligoanalgesia in a rural emergency department

Introduction

The term “oligoanalgesia” has been used to describe the phenomenon of poor pain management through the underuse of analgesia.\(^1\)\(^-\)\(^5\) In many cases, pain is the primary motive for a patient’s presentation to the emergency department (ED).\(^6\)\(^-\)\(^1\)\(^1\)\(^1\) It has been well-documented that numerous patients presenting to the ED receive little or no analgesia to manage their pain.\(^1\)^\(^2\)\(^-\)\(^1\)\(^5\) Several factors are thought to contribute to this poor pain management. Children are less likely than adults to receive analgesics in the ED.\(^2\)\(^,\)\(^1\)\(^1\) Ethnicity is also felt to play a role in oligoanalgesia.\(^3\)\(^,\)\(^4\)\(^,\)\(^1\)\(^6\)\(^,\)\(^1\)\(^7\) Lack of health insurance is another factor shown to result in less analgesia provided in the ED.\(^1\)\(^6\)

Many studies that demonstrate oligoanalgesia have been conducted in urban EDs.\(^1\)\(^-\)\(^1\)\(^1\)\(^4\)\(^,\)\(^1\)\(^6\)\(^,\)\(^1\)\(^8\)\(^-\)\(^2\)\(^0\) No studies that investigated oligoanalgesia in a rural ED setting were identified in a PubMed literature search. However, National Ambulatory Care Reporting System (NACRS) data for South Huron Hospital showed patients were satisfied with the amount of pain medicine they received in this rural ED. Patients reported that the “right amount of pain medicine was received in ED” (89%) and that the “ED did all it could to control pain” (62%).

Data from the NACRS report raised the hypothesis that pain was better addressed in a rural ED. To investigate this hypothesis, we performed a retrospective chart review of patients who presented to the South Huron Hospital ED with isolated lower limb injuries for 2003. This study was based on and compared with a previous study by Kozlowski and colleagues,\(^2\)\(^0\) which showed that pain was poorly addressed for this type of trauma in an urban ED. The purpose of our study was to see if oligoanalgesia was also an issue in our rural ED.

Methods

Approval for the retrospective chart review was obtained from the South Huron Hospital Medical Advisory Board. A search of the radiology department’s computer database identified patients who presented to the ED between Jan. 1 and Dec. 31, 2003, for whom radiographs of the foot, ankle or both were requested. The majority of radiographs were ordered by attending physicians, though some were requested by the triage nurse in accordance with the Ottawa Ankle Rules.\(^2\)\(^1\) Exclusion criteria included patients presenting without acute trauma, patients with multiple trauma or patients for whom radiographs were taken for follow-up assessment, after diagnosis of fractures.

Multiple data points were obtained from each chart, including basic demographic information. Times of patient registration, physician assessment and discharge from the ED were collected, along with the Canadian Emergency Department Triage and Acuity Scale (CTAS) level assigned by the triage nurse.\(^2\)\(^2\) The presence or absence of fracture was recorded. Whether or not the patient received analgesia before arrival to the ED, in the ED or upon discharge from the ED was quantified. In addition, the type of analgesia that was provided at discharge and whether it required a prescription was noted.
Results

A total of 228 patient charts were pulled for patients who had radiographs of the foot, ankle or both. There were 39 charts that met the exclusion criteria. Of these charts, 9 were excluded because the patient’s chief complaint was something other than acute trauma. Fifteen charts were excluded because the patients presented with multiple trauma, and a further 15 charts were excluded because the patients presented for follow-up or cast removal visits. This resulted in 189 patient charts that were included in the entire data cohort. The data shown in Table 1 were obtained and subsequently broken down into subgroups.

CTAS = Canadian Emergency Department Triage and Acuity Scale; SD = standard deviation.

About 13% of patients reported taking some form of analgesia before presenting to the ED. Overall, roughly 18% of patients were given some form of analgesia in the ED. However, when a fracture was identified by the physician, a patient was given analgesia roughly 3 times more often than a patient without a fracture, while still in the ED (46% v. 14%). Over 50% of all patients received some form of analgesia, advice or a prescription for analgesia upon discharge from the ED. This was independent of whether or not a fracture was identified (Fig. 1).

Analgesia that can be obtained over-the-counter (OTC) was recommended to patients without a fracture more often than analgesia that requires a prescription. Alternatively, patients with a fracture received a prescription for analgesia nearly 3 times more often than they received a recommendation for OTC analgesia (Fig. 2).

Upon discharge from the ED, almost 40% of patients without fractures were most often advised to use OTC nonsteroidal anti-inflammatory drugs (NSAIDs) to address their pain. Patients without fractures only received a narcotic prescription 6% of the time (Fig. 3) upon discharge. In contrast, patients with fractures received a prescription for narcotics more than 4 times as often (26% v. 6%) upon discharge (Fig. 4).

Discussion

When a fracture was identified, physicians in a rural ED were twice as likely as physicians in an urban ED to provide medication in the ED (46% v. 23%)

Fig. 1. The administration of analgesia for the entire cohort and broken down by presence or absence of fracture. ED = emergency department.

Fig. 2. Analgesia prescribed on discharge for the entire cohort and by presence of fracture. Patients may receive one or both types of analgesia.
and twice as likely to give a prescription when the patient was discharged (73% v. 36%). Therefore, oligoanalgesia was not observed as often in our rural ED for isolated lower limb injuries when compared with the previous urban study by Kozlowski and colleagues.20

Only one-half of the rural patients reported taking pain medication before arriving at the ED, compared with one-quarter of the patients in the urban study. This might explain why more rural patients received pain medication in the ED. However, this does not explain why patients with fractures were twice as likely to receive a prescription for pain medication upon discharge.

When a fracture was not diagnosed, analgesia was provided about 14% of the time in both settings. However, twice as many patients treated in the rural ED were given a prescription upon discharge compared with the urban ED (52% v. 27%). This again indicates that pain, with or without fracture, was more aggressively treated in this rural environment.

About 50% of patients, with or without fracture, received either a prescription or a recommendation to use OTC medication for their pain. The identification of a fracture did change physician prescribing habits. Prescription medication was used more often than OTC medication if a fracture was identified. The type of prescription provided was also different if a fracture was identified. Narcotics, compared with NSAIDs, were 4 times more likely to be prescribed at discharge when a fracture was diagnosed.

Patients presenting to our rural ED with an isolated lower limb injury were also managed in a timely manner. The mean time to physician assessment was about 30 minutes for patients presenting with an average CTAS score of 4.4. This is a shorter wait time than the guideline of 60 minutes for a CTAS-IV patient.25 It is also shorter than the median wait time found in Ontario EDs of 54 minutes for a CTAS-IV patient.25 The mean length of stay (LOS) in our study was also significantly shorter. Ontario ED patients had a median LOS of 100 minutes, compared with 74 minutes for patients in our rural ED.25

The times found in this study were also better than those reported by Todd and colleagues,18 who looked at patients with painful conditions presenting to 2 urban EDs. Their study reported that the mean time to analgesic, if it was provided, was 116 minutes and that the mean LOS was 240 minutes. So patients arriving in our rural ED with painful conditions were assessed, treated and discharged quickly, when compared with national guidelines, provincial statistics and urban EDs.

Why does it appear that isolated lower leg injuries are more aggressively treated in this rural setting compared with a similar urban study and other urban studies investigating oligoanalgesia? One reason could be that the volume of patients presenting to the rural ED is much smaller. This facility has about 10 000 ED visits per year. It is staffed by 1 physician and 2 registered nurses. Patients are seen much more quickly in this setting.24 The patient with the lower limb injury may very well be the only person in the ED. Therefore,
he or she may get much closer personal attention and his or her pain may be recognized more quickly.

The physical size of a small ED could also contribute to pain being recognized and treated more aggressively. The rural ED in our study has 3 treatment rooms and 1 treatment chair. The nurses and doctor can see all of the patients from the desk. The imaging department is across the hall. These close settings allow the staff to observe the patients closely and monitor their pain.

Only 18.5% of patients imaged had fractures identified in the rural setting, compared with 35% in the urban setting. The patient in the rural ED with a fractured ankle may be the only fracture seen that day and could very well represent the most painful condition seen for the entire shift. Therefore, this may lead the ED physician to treat this painful condition more aggressively.

Another reason for using twice the analgesia in the rural ED and upon discharge could be the familiarity of the staff with the patients. The patients presenting to the rural ED are mostly members of the small town and surrounding farm community. Chances are that someone from the hospital staff will either know the patient personally or be related to him or her. This might create an environment of greater empathy for patients’ pain.

Training of the attending physicians in the rural ED could also play a role in better pain management in the ED. Family physicians who have completed a 2-year residency, with or without a third year option in emergency medicine, staff most Canadian rural EDs. Our ED is staffed only by family medicine–trained physicians, with many practising primary care within the community. These general practitioners may be more sensitive to their patients’ painful conditions.

Patients presenting with their painful injury may be treated by their personal physician. This may lead to the duty doctor recognizing a patient’s pain and treating it more aggressively. These physicians may also be more comfortable prescribing narcotics because they know the patients well and will be seeing them for follow-up.

There were limitations of this study inherent in its retrospective chart review design. Some physicians documented whether analgesia was offered to the patient but was declined, while other physicians did not document if analgesia was offered. Also, it is difficult to determine directly if patients got enough analgesia when it was offered because it was not documented whether patients were asked if their pain was better. Further studies should be done at other rural EDs to see if this observation was an isolated finding. In addition, a prospective study could be designed to see if other painful conditions are more aggressively treated in a rural setting.

While this study was very encouraging, there is still room for improvement. About 50% of patients with fractures did not receive any pain medication in the ED or on discharge from the ED. To reach these patients who did not receive any analgesia we exhort the Canadian Association of Emergency Physicians to incorporate a pain score as part of the vital signs assessment.

**Conclusion**

Patients presenting with painful isolated lower limb injuries are assessed, treated and discharged quickly in our rural ED. These patients are also twice as likely to receive pain medication in the ED and upon discharge, compared with the published urban study. This suggests the phenomenon of oligoanalgesia is less of a problem in our rural ED.
